

Objective & Lecture Mapping: In previous labs, we built a Simple Reflex Agent that moved randomly or reacted only to immediate adjacent cells. Today, we transition to a **Goal-Based/Planning Agent**. You will expose the environment's state space to the agent, allowing it to use **Breadth-First Search (BFS)**, **Depth-First Search (DFS)**, and **Uniform-Cost Search (UCS)** to simulate and find paths to the food before taking a physical action.

Part 1: Practical Implementation — Building the Search Agent

Step 1.1: Exposing the World Model

Classical search algorithms require an abstract model of the environment to simulate future states. Currently, your agent is "blind" to the overall map.

1. Create a new Branch called Week_03 in your Forked Github Repo and work on the below Questions.
2. Open `visual_grid_game.py` .
3. Locate the `get_percept(self)` method.
4. Add three new keys to the dictionary to pass the global state to the agent:

```
'grid_size': (self.width, self.height)
'walls': list(self.walls)
'all_food': list(self.food_positions)
```

Step 1.2: Implementing BFS, DFS, and UCS

You will implement three distinct uninformed search strategies. The core node expansion structure is identical; only the data structure for the **Frontier** changes!

1. Open `agent.py` and create a new class called `SearchAgent` .
2. Import required structures: `from collections import deque` and `import heapq` .
3. **BFS:** Create `def bfs_search(...)` . Use a FIFO queue (`deque.popleft()`). This explores the shallowest nodes first.
4. **DFS:** Create `def dfs_search(...)` . Use a LIFO stack (`list.pop()`). This explores the deepest nodes first.
5. **UCS:** Create `def ucs_search(...)` . Use a Priority Queue (`heapq.heappop()`) ordered by the total path cost $g(n)$.
6. For all three algorithms, you must maintain a `reached` set (or visited array) to track explored states. This converts your algorithm from a *Tree Search* to a *Graph Search*, preventing infinite loops.

Step 1.3: Executing and Comparing Offline Plans

The agent must now form a complete plan and execute it step-by-step.

1. In your `SearchAgent.__init__` , add an empty list: `self.plan = []` and a config string `self.active_algo = 'BFS'` .
2. In `sense_and_act(self, percept)` , check if `self.plan` is empty.
3. If empty, find the closest food pellet from `percept['all_food']` , execute the search method matching `self.active_algo` , and store the resulting sequence of actions in `self.plan` .
4. Return the first action from the plan using `return self.plan.pop(0)` .
5. **Observation Task:** Change `self.active_algo` between 'BFS', 'DFS', and 'UCS' and run the simulation. Watch how DFS takes erratic, winding paths, while BFS and UCS take direct, optimal paths!

Part 2: Theoretical Evaluation

Based on your implementation and Lecture 04, complete the following analytical questions.

1. (Remember) You built your search logic based on the environment coordinates. What is the fundamental difference between the "State Space" and the "Search Tree"?

The state space is the collection of all possible valid states in the environment. In our grid game, each valid coordinate represents a state. The search tree is the structure created by the search algorithm while exploring different paths from the starting state to the goal. The same state can appear more than once in the search tree if it is reached through different paths.

2. (Understand) In Step 1.2, you were instructed to use a 'reached' set. In graph search theory, what specific problem does this set solve, and what would happen to your DFS agent without it?

The reached set keeps track of states that have already been explored. This prevents the search algorithm from repeatedly visiting the same positions and creating cycles. Without the reached set, DFS could keep visiting the same cells again and again, get stuck in an infinite loop, and possibly never reach the food.

3. (Analyze) Compare the visual paths generated by BFS and DFS in your simulation. Why is BFS guaranteed to be optimal in this specific grid, whereas DFS produces winding, suboptimal routes?

BFS explores the grid level by level, so it checks shorter paths before longer paths. In our grid, every movement has the same cost, so the first path BFS finds to the food will have the minimum number of steps. DFS works differently because it follows one path as deeply as possible before trying another path. Because of this, DFS can take a long and winding route even when a much shorter path to the food exists.

4. (Evaluate) If we scaled `visual\_grid\_game.py` up to a massive 1000x1000 grid, BFS and UCS might crash before finding food. According to the time and space complexity formulas from the lecture, contrast the memory bottlenecks of BFS versus DFS.

BFS requires a large amount of memory because it has to keep many nodes from the current search level in memory at the same time. Its space complexity is approximately $O(b^d)$, where b is the branching factor and d is the depth of the shallowest solution. DFS uses less memory because it mainly stores the current path and the remaining branches. Its space complexity is approximately $O(bm)$, where m is the maximum search depth. Therefore, on a very large 1000x1000 grid, BFS and UCS may run out of memory, while DFS is more memory efficient. However, DFS does not guarantee that it will find the shortest path.
